Extracorporeal membrane oxygenation in pregnant and postpartum women: a ten-year case series

Carolyn M. Webster, MD; Kathleen A. Smith, MD; Tracy A. Manuck, MD, MS

OBJECTIVE: Extracorporeal membrane oxygenation (ECMO) is a life-saving therapy for severe, reversible cardiopulmonary failure, but data regarding its use in pregnancy and the postpartum period are limited. We sought to quantify survival of pregnant and postpartum women necessitating ECMO in a contemporary cohort at a single tertiary institution.

STUDY DESIGN: All women of reproductive age (14–44 years), who underwent ECMO at our institution between January 1, 2008, and December 31, 2017, were identified using a query of hospital encounters for ECMO-related CPT codes. We manually reviewed all charts of women of reproductive age; women who were pregnant or <6 weeks postpartum at the time of ECMO initiation were included. Clinical characteristics and maternal and fetal outcomes are described.

RESULTS: In this study, 54 women of reproductive age underwent ECMO for cardiopulmonary failure. Of those, 9 (17%) were pregnant or <6 weeks postpartum at the time of ECMO initiation: 4 antepartum, 1 intraoperative at the time of cesarean delivery, and 4 postpartum (including 2 in whom ECMO was initiated on postpartum day 0 or 1). Overall, maternal survival was 33%. The median maternal age was 24 years (range 19–39 years); most women were nonsmokers without underlying medical comorbidities. The most common indication for ECMO use in pregnant and postpartum women was acute respiratory distress syndrome, which was present in 7 cases (78%), including 5 cases that were due to infectious etiologies and 2 cases that were attributed to preeclampsia. The median number of days on ECMO was 6 (range 1–14). There were no cases of obstetric hemorrhage. Venovenous ECMO was utilized in all but 1 case, in which emergent attempted venoarterial ECMO was unsuccessful in resuscitating a postpartum patient with cardiac arrest and a massive pulmonary embolism. A total of 4 women were initiated on ECMO during pregnancy: their gestational ages at ECMO initiation were 21, 22, 29, and 30 weeks; maternal survival was 50%, and fetal mortality was 50%. A case of ECMO initiated during cesarean section at 29 weeks’ gestation resulted in both maternal and fetal survival. Among 4 mothers with ECMO initiation after childbirth, none survived. Finally, we found a tendency toward survival in those patients for whom ECMO was initiated soon after mechanical ventilation, earlier in the disease process. In contrast, in this study, 23 of 45 women of reproductive age (51%) who were not pregnant but underwent ECMO survived.

CONCLUSION: When ECMO was initiated during pregnancy or during childbirth, 60% of mothers and fetuses survived, supporting current use of ECMO as a salvage therapy in pregnant and intrapartum women. In this generally young and healthy population, ECMO has the potential to increase the survival rates of both mother and fetus and should be considered a salvage therapy for peripartum women with reversible forms of cardiorespiratory failure.

Key words: critical care, pregnancy, respiratory failure, hypoxemia, extracorporeal membrane oxygenation

Introduction

Extracorporeal life support was first introduced as a life-saving therapy in the 1970s. After its debut, randomized controlled trials initially showed benefit only in neonates, with survival approaching 80% in this population, compared with 10% to 30% of adults receiving therapy. However, technological improvements, including heparin coating of equipment in the years 1990 to 2000, led to improved outcomes in adults, and currently, survival rates in adults are 50% to 70%. Modern extracorporeal membrane oxygenation (ECMO) is utilized in many tertiary care centers across the United States and other developed countries as a life-saving technology for severe, reversible cardiopulmonary failure. According to the Extracorporeal Life Support Organization (ELSO), the past decade has seen an increase in ECMO use in adults by more than 10-fold, and rates of use continue to rise. Use of ECMO in adults worldwide in 2019 exceeded 12,000 cases, an increase of 30% from the previous year.5

Despite its widespread use, there are limited data regarding the safety and efficacy of ECMO when used in pregnant and postpartum patients. We reviewed the literature and estimated that fewer than 150 cases of ECMO use during pregnancy and the postpartum period have been published. The largest case series we are aware of consists of 18 women (4 pregnant and 14 postpartum); many publications are single case reports. Although the ELSO closely monitors outcomes and complication rates among individuals receiving ECMO, they do not track pregnancy or postpartum status. Therefore, the purpose of this study is to add to the literature by providing additional cases of ECMO use in obstetric patients to further support claims of safety and efficacy when used in pregnant and postpartum women.

Material and Methods

This was a 10-year case series (2008–2017) of pregnant and postpartum women undergoing ECMO at our tertiary care institution. Cases were identified using a query of all hospital encounters for ECMO-related CPT codes in adolescents and/or women aged 14 to 44 years. Individual chart review was then performed to confirm ECMO utilization for cardiopulmonary failure.
and to identify patients with a confirmed intrauterine pregnancy of at least 6 weeks’ gestation at the time of ECMO initiation and up to 6 weeks postpartum. Clinical characteristics and maternal and/or fetal outcomes were abstracted via individual chart review.

Our primary outcome of interest was maternal survival. The secondary outcome of interest was fetal survival if the mother was pregnant at the time of ECMO initiation. Additional characteristics of interest included indication for ECMO, type of ECMO circuit (venovenous or venoarterial), clinical parameters prompting providers to initiate mechanical ventilation and ECMO, length of time on ECMO, and time on mechanical ventilation before ECMO cannulation. Obstetric characteristics were also collected, including gestational age, mode and timing of delivery, and postpartum hemorrhage. Survival was also recorded for the women of reproductive age identified by our query who were not pregnant or who were postpartum women. Descriptive analyses are reported.

This study was reviewed and approved by the institutional review board at the University of North Carolina-Chapel Hill under a waiver of informed consent.

**Results**

In this study, a total of 54 women of reproductive age underwent ECMO for cardiopulmonary failure, and of these, 9 (17%) were pregnant or postpartum. These cases included 4 women who were pregnant at the time of ECMO initiation, 1 who had ECMO cannulation during birth (cesarean delivery), and 4 who were postpartum (Table 1). The median maternal age was 24 (range 19–39) years. Among the 9 women, 7 (78%) were nonsmokers, and 5 (56%) self-identified as non-Hispanic black. Only 2 patients had medical history notable for underlying medical comorbidities: one with type 1 diabetes mellitus and the other with severe asthma.

The most common indication for ECMO use in pregnancy and the postpartum period was ARDS, which was present in 7 of 9 (78%) cases, wherein 5 were due to infectious etiologies and 2 were attributed to preeclampsia. Among the 9 women, 6 (67%) underwent ECMO cannulation within 24 hours of initiation of mechanical ventilation, with timing ranging from <1 hour to 11 days (Table 1). Major clinical parameters present at the time of decision for mechanical ventilation and ECMO initiation are listed in Table 2. Venovenous ECMO was utilized in all but 1 case and was most often initiated owing to persistent hypoxemia despite maximal ventilatory settings or because of the significant risk of secondary lung injury from barotrauma, caused by high airway pressures required to maintain oxygenation. The single case of venoarterial ECMO was an unsuccessful resuscitation of a postpartum patient who had cardiac arrest with a massive pulmonary embolism. Women received ECMO for a median of 6 (range 1–14) days.

The timing and duration of ECMO relative to obstetric outcomes are shown in Figure 1. Four women were pregnant at the time of ECMO initiation; the gestational ages of these 4 women at the time of ECMO cannulation were 21, 22, 29, and 30 weeks. One additional patient underwent ECMO cannulation intraoperatively during an emergent cesarean delivery at 29 weeks’ gestation. The remaining women were between 0 and 36 days postpartum at the time of ECMO initiation. Among the postpartum women, pregnancy durations ranged from 12 weeks to full term. In addition to the aforementioned cesarean delivery, there were 2 additional deliveries that used ECMO, both owing to preterm labor—one with spontaneous vaginal delivery of a preivable twin gestation and the other with forceps-assisted vaginal delivery of a preterm infant. There were no cases of obstetric hemorrhage.

Overall, 3 of 9 (33%) mothers survived. All 3 surviving patients were either pregnant or intrapartum at the time of ECMO cannulation, whereas none of the patients who initiated ECMO postpartum survived. In addition, in 5 of 9 women in whom ECMO was initiated while pregnant and/or intrapartum, maternal survival was 60%, and fetal survival was 60%; both mother and fetus survived in 2 pregnancies (40%).

Of the 3 surviving women, 1 woman had 1 subsequent pregnancy in our healthcare institution. She had an uncomplicated term delivery of an appropriate for gestational age neonate 21 months after her hospital discharge from her pregnancy requiring ECMO.

none of the pregnant women who had complicated pregnancies owing to severe maternal illness requiring ECMO during pregnancy or intrapartum delivered at term. Specifically, rates of spontaneous preterm labor and nonreassuring fetal status were high.

Despite a relative paucity of data in the obstetric population and the low maternal survival rate in this cohort, ECMO remains an attractive life-saving therapy for severe, reversible cardiopulmonary failure. Despite the full anticoagulation strategies required during ECMO, none of the antepartum or postpartum cases were complicated by obstetric hemorrhage. Although pregnant and postpartum women have unique risks for both infectious and noninfectious respiratory failure, most women in this study were young and lacked extensive medical comorbidities. Our case of emergent intrapartum ECMO initiation due to flash pulmonary edema and refractory hypoxemia and hypercarbia secondary to preeclampsia with severe features exemplifies a clinical scenario unique to pregnancy and illustrates a situation where tertiary care resources can be mobilized in nontraditional ways to meet acute patient needs. Furthermore, several women in our case series underwent ECMO initiation after only a short period of mechanical ventilation. There was a tendency toward survival in those patients for whom ECMO was initiated soon after mechanical ventilation, earlier in the disease process. Of the 3 patients who survived, all were cannulated for ECMO within 14 hours (range 1.5–14 hours) of intubation and mechanical ventilation, compared with non-survivors who were cannulated for ECMO later (range <1 hour—11 days).

Pregnancies complicated by ARDS, regardless of need for ECMO, are associated with a high rate of both maternal mortality (range 6.3%–76.2%) and perinatal mortality (range 8.3%–43.5%).\(^{20-29}\) In a pooled analysis of 9 reports\(^{6,9,13-19}\) of 78 pregnant or postpartum women receiving ECMO (where each publication included at least 3 patients; range 3–18), the overall maternal mortality rate was 22.8% (95% confidence interval, 11.6%–35.9%), a rate lower than that of the general adult population that received ECMO.\(^{30}\) In addition, other single case reports of ECMO in pregnancy were published, the vast majority of which reported successful outcomes.\(^{7-12}\) The wide range of outcomes in previous reports may reflect differences in patient-level factors and specific underlying etiologies of ARDS, in addition to publication biases. We posit that the differences we found in maternal outcomes in our cohort of women who received ECMO may reflect the unbiased reporting of all cases at our institution. In addition, other patientspecific and system-specific factors (eg, the underlying reason for ECMO, at what point in the disease process the individual was placed on ECMO, and other concomitant treatments) may explain the observed differences in outcomes.

Although pregnancy does not appear to influence the overall survival of women who develop ARDS, there are several key physiological differences in pregnancy that must be considered when caring for the critically ill pregnant patients.\(^{21}\) Reports regarding ventilatory management of ARDS in pregnancy suggest that pregnant women are more likely to develop severe ARDS requiring high ventilatory pressures. This is not unexpected, as the gravid uterus increases intraabdominal pressure, displaces the diaphragm upward, and reduces chest wall compliance.\(^{31}\) In addition to higher peak airway pressures required in pregnancy, accepted lung protective ventilatory strategies in ARDS, particularly permissive hypercapnia and associated respiratory acidosis, are at odds with fetal well-being and survival. It is possible that initiating ECMO early in the course of worsening ARDS may improve both maternal and fetal outcomes, compared with mechanical ventilation alone.

This study has several strengths. Our study is one of only a small number of case series\(^{6,9,13-19}\) to report on outcomes of a comprehensive case series of pregnant and postpartum women receiving ECMO and adds to the growing body of literature in this area. Our comprehensive chart review permitted evaluation of multiple medical and pregnancy-
specific factors that may have influenced outcomes and also permitted us to describe in detail the specific conditions leading to deterioration of health of the patients resulting in both mechanical ventilation and ECMO. In addition, manual review of all records of women of reproductive age who received ECMO ensured that we were able to capture all pregnant and postpartum women, reducing the risk for a positive reporting bias. Nonetheless, these data should be interpreted with caution. Assessing outcomes in this population is limited by many factors, including the relative rarity of ECMO use and the difficulty in identifying and tracking pregnancy status in those undergoing ECMO. Furthermore, although this represents one of the largest case series to date on ECMO use in pregnancy and the postpartum period, numbers remain small.

Conclusion

In conclusion, ECMO is a key, potentially life-saving treatment for severe cardiopulmonary failure. Despite high maternal and perinatal mortality rates, therapy should not be withheld during pregnancy or the postpartum period. In this generally young and healthy population, ECMO has the potential to improve the survival rates of both mother and fetus and should be considered a salvage therapy for pregnant women with reversible forms of cardiorespiratory failure. We also noted a tendency toward survival in those patients whom ECMO was initiated soon after mechanical ventilation, earlier in the disease process. Obstetric clinicians should remain vigilant for the possibility of spontaneous preterm labor and nonreassuring fetal status. To better assess outcomes in this population, we implore the ELSO, which closely tracks ECMO cases in the United States, to consider tracking pregnancy and postpartum status.
